DISCLAIMER

This report has been reviewed by the Environmental Criteria and Assessment Office, U.S. Environmental Protection Agency, and approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

AVAILABILITY NOTICE

This document is available to the public through the National Technical Information Service, (NTIS), Springfield, Virginia 22161.

FOREWORD

Section 304 (a)(1) of the Clean Water Act of 1977 (P.L. 95-217), requires the Administrator of the Environmental Protection Agency to publish criteria for water quality accurately reflecting the latest scientific knowledge on the kind and extent of all identifiable effects on health and welfare which may be expected from the presence of pollutants in any body of water, including ground water. Proposed water quality criteria for the 65 toxic pollutants listed under section 307 (a)(1) of the Clean Water Act were developed and a notice of their availability was published for public comment on March 15, 1979 (44 FR 15926), July 25, 1979 (44 FR 43660), and October 1, 1979 (44 FR 56628). This document is a revision of those proposed criteria based upon a consideration of comments received from other Federal Agencies, State agencies, special interest groups, and individual scientists. The criteria contained in this document replace any previously published EPA criteria for the 65 pollutants. This criterion document is also published in satisfaction of paragraph 11 of the Settlement Agreement in Natural Resources Defense Council, et. al. vs. Train, 8 ERC 2120 (D.D.C. 1976), modified, 12 ERC 1833 (D.D.C. 1979).

The term "water quality criteria" is used in two sections of the Clean Water Act, section 304 (a)(1) and section 303 (c)(2). The term has a different program impact in each section. In section 304, the term represents a non-regulatory, scientific assessment of ecological effects. The criteria presented in this publication are such scientific assessments. Such water quality criteria associated with specific stream uses when adopted as State water quality standards under section 303 become enforceable maximum acceptable levels of a pollutant in ambient waters. The water quality criteria adopted in the State water quality standards could have the same numerical limits as the criteria developed under section 304. However, in many situations States may want to adjust water quality criteria developed under section 304 to reflect local environmental conditions and human exposure patterns before incorporation into water quality standards. It is not until their adoption as part of the State water quality standards that the criteria become regulatory.

Guidelines to assist the States in the modification of criteria presented in this document, in the development of water quality standards, and in other water-related programs of this Agency, are being developed by EPA.

STEVEN SCHATZOW
Deputy Assistant Administrator
Office of Water Regulations and Standards

CRITERIA DOCUMENT
CHLOROALKYL ETHERS

CRITERIA

Aquatic Life

The available data for chloroalkyl ethers indicate that acute toxicity to freshwater aquatic life occurs at concentrations as low as 238,000 $\mu\text{g/l}$ and would occur at lower concentrations among species that are more sensitive than those tested. No definitive data are available concerning the chronic toxicity of chloroalkyl ethers to sensitive freshwater aquatic life.

No saltwater organism has been tested with any chloroalkyl ether and no statement can be made concerning acute or chronic toxicity.

Human Health

For the protection of human health from the toxic properties of bis(2-chloroisopropyl) ether ingested through water and contaminated aquatic organisms, the ambient water criterion is determined to be 34.7 $\mu\text{g/l}$.

For the protection of human health from the toxic properties of bis(2-chloroisopropyl) ether ingested through contaminated aquatic organisms alone, the ambient water criterion is determined to be 4.36 mg/l .

For the maximum protection of human health from the potential carcinogenic effects due to exposure of bis(chloromethyl) ether through ingestion of contaminated water and contaminated aquatic organisms, the ambient water concentrations should be zero based on the non-threshold assumption for this chemical. However, zero level may not be attainable at the present time. Therefore, the levels which may result in incremental increase of cancer risk over the lifetime are estimated at 10^{-5} , 10^{-6} , and 10^{-7} . The

corresponding recommended criteria are 37.6×10^{-6} $\mu\text{g/l}$, 3.76×10^{-6} $\mu\text{g/l}$, and 0.376×10^{-6} $\mu\text{g/l}$, respectively. If the above estimates are made for consumption of aquatic organisms only, excluding consumption of water, the levels are 18.4×10^{-3} $\mu\text{g/l}$, 1.84×10^{-3} $\mu\text{g/l}$, and 0.184×10^{-3} $\mu\text{g/l}$, respectively.

For the maximum protection of human health from the potential carcinogenic effects due to exposure of bis(2-chloroethyl) ether through ingestion of contaminated water and contaminated aquatic organisms, the ambient water concentrations should be zero based on the non-threshold assumption for this chemical. However, zero level may not be attainable at the present time. Therefore, the levels which may result in incremental increase of cancer risk over the lifetime are estimated at 10^{-5} , 10^{-6} , and 10^{-7} . The corresponding recommended criteria are 0.30 $\mu\text{g/l}$, 0.030 $\mu\text{g/l}$, and 0.003 $\mu\text{g/l}$, respectively. If the above estimates are made for consumption of aquatic organisms only, excluding consumption of water, the levels are 13.6 $\mu\text{g/l}$, 1.36 $\mu\text{g/l}$, and 0.136 $\mu\text{g/l}$, respectively.

INTRODUCTION

The chloroalkyl ethers have been widely used in laboratories and in industrial organic synthesis, textile treatment, preparation of ion exchange resins, and pesticide manufacture. They also have been used as solvents for polymerization reactions (Summers, 1955).

The chloroalkyl ethers are compounds with the general structure $RC1x-O-R' Clx$, where x may be any positive integer, including zero, and R and R' are aliphatic groups. The chemical reactivity of these compounds varies widely, depending on the placement of chlorine atoms and the nature of the aliphatic groups involved. Chloromethylmethyl ether, bis(chloromethyl) ether, 1-chloroethylethyl ether, and 1-chloroethylmethyl ether decompose in water (Hampel and Hawley, 1973). Tou and Kallos (1974) calculated a half-life of 14 seconds for bis(chloromethyl) ether in aqueous solution. Chloromethylmethyl ether undergoes decomposition in water to form methanol, formaldehyde, and hydrochloric acid. Bis(chloromethyl) ether will form spontaneously in the presence of hydrogen chloride and formaldehyde (Frankel, et al. 1974).

The general physical properties of bis(2-chloroisopropyl) ether are as follows.

Molecular weight (Weast, 1977)	171.07
Melting point (Verschueren, 1977)	-97°C
Boiling point at 760 torr (Verschueren, 1977)	189°C
Vapor pressure at 20°C (Verschueren, 1977)	0.85 torr

Solubility in water* (Verschueren, 1977)	1,700 mg/l
Log octanol/water partition coefficient (Leo, et al. 1971)	2.58

The general physical properties of bis(2-chloroethyl) ether are as follows.

Molecular weight (Weast, 1977)	143.02
Melting point (Weast, 1977)	-46.8°C
Boiling point at 760 torr (Weast, 1977)	178°C
Vapor pressure at 20°C (Verschueren, 1977)	0.71 torr
Solubility in water* (Verschueren, 1977)	10,200 mg/l
Log octanol/water partition coefficient (Leo, et al. 1971)	1.58

*Experimental data generated at room temperature; no specific temperature reported.

The general physical properties of bis(chloromethyl) ether are as follows.

Molecular weight (Weast, 1977)	114.96
Melting point (Weast, 1977)	-41.5°C
Boiling point at 760 torr (Weast, 1977)	104°C
Vapor pressure at 22°C (Dreisbach, 1952)	30 torr
Solubility in water at 25°C (calc. by method of Moriguchi, 1975 using the data of Quayle, 1953)	22,000 mg/l
Log octanol/water partition coefficient (calc. by Radding, et al. 1977)	-0.38

The general physical properties of 2-chloroethyl vinyl ether are as follows.

Molecular weight (Weast, 1977)	106.55
Melting point	No data found
Boiling point at 760 torr (Weast, 1977)	108°C
Vapor pressure at 20°C (calc. from Dreisbach, 1952)	26.75 torr
Solubility in water at 25°C (calc. by method of Moriguchi, 1975)	15,000 mg/l
Log octanol/water partition coefficient (calc. by method of Leo, et al. 1971)	1.28

The general physical properties of bis(2-chloroethoxy) methane are as follows.

Molecular weight (Webb, et al. 1962)	173.1
Melting point	No data found
Boiling point at 760 torr (Webb, et al. 1962)	218.1°C*
Vapor pressure at 20°C (calc. from Dreisbach, 1952 based on the data of Webb, et al. 1962)	<0.1 torr
Solubility in water at 25°C (calc. by method of Moriguchi, 1975)	81,000 mg/l
Log octanol/water partition coefficient (calc. based on method of Leo, et al. 1971)	1.26

*The boiling point at 760 torr has been reported as 105 to 106° by Durkin, et al. (1975). Based on the detailed study of Webb, et al. (1962) on the properties of this pollutant and other compounds in this series, the value reported by Durkin, et al. (1975) is incorrect.

INTRODUCTION

The data base for freshwater organisms and chloroalkyl ethers is limited to a few toxicity tests with bis(2-chloroethyl) ether and one with 2-chloroethyl vinyl ether. No LC_{50} or EC_{50} values were observed below 238,000 $\mu\text{g/l}$. Bioconcentration of bis(2-chloroethyl) ether by the bluegill was low.

No appropriate data are available for saltwater organisms and any chloroalkyl ether.

EFFECTS

Acute Toxicity

A 48-hour EC_{50} value for Daphnia magna was determined to be 238,000 $\mu\text{g/l}$ for bis(2-chloroethyl) ether (Table 1).

No 96-hour LC_{50} value for the bluegill could be determined for bis(2-chloroethyl) ether in a test with exposure concentrations as high as 600,000 $\mu\text{g/l}$ (Table 4).

The 96-hour LC_{50} for the bluegill and 2-chloroethyl vinyl ether is 354,000 $\mu\text{g/l}$ (U.S. EPA, 1978) (Table 1).

Chronic Toxicity

An embryo-larval test has been conducted with bis(2-chloroethyl) ether and the fathead minnow (U.S. EPA, 1978). No adverse effects were observed at test concentrations as high as 19,000 $\mu\text{g/l}$ (Table 2).

*The reader is referred to the Guidelines for Deriving Water Quality Criteria for the Protection of Aquatic Life and Its Uses in order to better understand the following discussion and recommendation. The following tables contain the appropriate data that were found in the literature, and at the bottom of each table are calculations for deriving various measures of toxicity as described in the Guidelines.

Plant Effects

No data are available on the effects of any chloroalkyl ether on aquatic plants.

Residues

Using ^{14}C -bis(2-chloroethyl) ether and thin layer chromatography (U.S. EPA, 1978), a steady-state bioconcentration factor of 11 was determined during a 14-day exposure of bluegill (Table 3). The half-life was observed to be between 4 and 7 days.

Miscellaneous

The only datum in Table 4 has been discussed previously.

Summary

Only a few tests have been conducted with freshwater organisms and chloroalkyl ethers. Results for 2-chloroethyl vinyl ether and bis(2-chloroethyl) ether suggest that acute and chronic toxicity occur at relatively high concentration and that bioconcentration is low.

CRITERIA

The available data for chloroalkyl ethers indicate that acute toxicity to freshwater aquatic life occurs at concentrations as low as 238,0090 $\mu\text{g/l}$ and would occur at lower concentrations among species that are more sensitive than those tested. No definitive data are available concerning the chronic toxicity of chloroalkyl ethers to sensitive freshwater aquatic life.

No saltwater organism has been tested with any chloroalkyl ether and no statement can be made concerning acute or chronic toxicity.

Table 1. Acute values for chloroalkyl ethers (U.S. EPA, 1978)

<u>Species</u>	<u>Method#</u>	<u>Chemical</u>	<u>LC50/EC50 (µg/l)</u>	<u>Species Acute Value (µg/l)</u>
		<u>FRESHWATER SPECIES</u>		
Cladoceran, <u>Daphnia magna</u>	S, U	Bis(2-chloro- ethyl) ether	238,000	238,000
Bluegill, <u>Lepomis macrochirus</u>	S, U	2-chloroethyl vinyl ether	354,000	354,000

* S = static, U = unmeasured

No Final Acute Values are calculable since the minimum data base requirements are not met.

Table 2. Chronic values for chloroalkyl ethers (U.S. EPA, 1978)

<u>Species</u>	<u>Method#</u>	<u>Chemical</u>	<u>Limits (µg/l)</u>	<u>Chronic Value (µg/l)</u>
<u>FRESHWATER SPECIES</u>				
<u>Fathead minnow, Pimephales promelas</u>	E-L	Bis(2-chloro- ethyl) ether	>19,000	-

* E-L = embryo-larval

No acute-chronic ratio can be calculated since no acute toxicity data are available for this species.

Table 3. Residues for chloroalkyl ethers (U.S. EPA, 1976)

<u>Species</u>	<u>Tissue</u>	<u>Chemical</u>	<u>Bioconcentration Factor</u>	<u>Duration (days)</u>
<u>Bluegill, Lepomis macrochirus</u>	whole body	Bis(2-chloro-ethyl) ether	11	14

FRESHWATER SPECIES

Table 4. Other data for chloroalkyl ethers (U.S. EPA, 1978)

<u>Species</u>	<u>Chemical</u>	<u>Duration</u>	<u>Effect</u>	<u>Result</u> ($\mu\text{g/l}$)
Bluegill, <u>Lepomis macrochirus</u>	<u>FRESHWATER SPECIES</u> Bis(2-chloro-ethyl) ether	96 hrs	LC50	>600,000

Mammalian Toxicology and Human Health Effects

INTRODUCTION

The chloroalkyl ethers, a subclass of haloethers, are widely used in industries and laboratories. Some of the members of this subclass are potent carcinogens, and some have been found in the aquatic environment. The chloroalkyl ethers discussed in this document are listed in Table 1. Of these compounds, bis(chloromethyl) ether (BCME), chloromethyl methyl ether (CMME), bis(2-chloroethyl) ether (BCEE), and bis(2-chloroisopropyl) ether (BCIE) have received the greatest attention because of their potential health hazards. Comprehensive reviews on the physical and chemical properties and biological effects of these chemicals have been published (Summers, 1955; Van Duuren, 1969; Int. Agency Res. Cancer, 1974, 1975; Durkin, et al. 1975; Nelson, 1976; NAS, 1977). The physical constants of the four environmentally important chloroalkyl ethers are summarized in Table 2. This document will be primarily concerned with the health effects of the chloroalkyl ethers listed in Table 2.

Because of their high reactivity, BCME and CMME have found wide laboratory and industrial use as intermediates in organic synthesis, in the treatment of textiles, for the manufacture of polymers and insecticides, in the preparation of ion-exchange resins, and in industrial polymerization reactions. Following recognition of the high potency of these chemicals as carcinogens by inhalation in animals, and various epidemiological evidence linking excessive human respiratory cancer incidence to exposure, BCME and CMME have been listed as two of the 14 carcinogens restricted by Federal

TABLE 1
Chloroalkyl Ethers Covered in this Document

Names, Abbreviations, and Synonyms	Chemical Formula
Chloromethyl methyl ether (CMME) other names: dimethylchloroether; methyl chloromethyl ether	$\text{ClCH}_2\text{OCH}_3$
Bis(chloromethyl) ether (BCME) other names: chloromethyl ether; chloro(chloromethoxy) methane; dichloromethyl ether; dimethyl-1,1-dichloroether	$\text{ClCH}_2\text{OCH}_2\text{Cl}$
α, α -Dichloromethyl methyl ether other name: 1,1-dichloromethyl methyl ether	$\text{Cl}_2\text{CHOCH}_3$
Bis(α -chloroethyl) ether other name: bis(1-chloroethyl)- ether	$\begin{array}{c} \text{CH}_3\text{CHOCHCH}_3 \\ \quad \\ \text{Cl} \quad \text{Cl} \end{array}$
Bis(2-chloroethyl) ether (BCEE) other names: 1,1'-oxybis(2-chloro)- ethane; bis(β -chloroethyl) ether; 1-chloro-2-(β -chloroethoxy)ethane; etc.	$\text{ClCH}_2\text{CH}_2\text{OCH}_2\text{CH}_2\text{Cl}$
Bis(2-chloroisopropyl) ether (BCIE) other name: bis(2-chloro-1-methyl- ethyl)ether	$\begin{array}{c} \text{ClCH}_2\text{CHOCHCH}_2\text{Cl} \\ \quad \\ \text{CH}_3 \quad \text{CH}_3 \end{array}$
2-Chloroethyl vinyl ether	$\text{ClCH}_2\text{CH}_2\text{OCH}=\text{CH}_2$
Octachloro-di-n-propyl-ether	$\begin{array}{c} \text{Cl}_3\text{CCHCH}_2\text{OCH}_2\text{CHCCl}_3 \\ \quad \\ \text{Cl} \quad \quad \text{Cl} \end{array}$

TABLE 2

Physical Constants of Four Environmentally Most Significant Chloroalkyl Ethers

Compound	Mol. Wt.	Appearance at room temperature	m.p.	b.p. (760 mm Hg)	Density	n_D^{20}	Solubility
CMME	80.5	colorless liquid		59°C	$d_4^{20} = 1.0605$	1.3974 ^c	Immediately hydrolyze in water; miscible with ethanol, ether and many other organic solvents.
BCME	115.0	colorless liquid		104°C	$d_4^{15} = 1.328$	1.435	Immediately hydrolyze in water; miscible with ethanol, ether and many other organic solvents.
BCEE	143.01	colorless liquid	-24.5°C ^a -51.9°C ^b	176-178°C	$d_4^{20} = 1.213$	1.457	Practically insoluble in water; miscible with most organic solvents (especially, benzene and chloroform)
BCIE	171.07	colorless liquid		187-188°C		1.4474	Practically insoluble in water; miscible with most organic solvents.

^a IARC (1975)^b Schrenk, et al. (1933)^c n for refractive index

regulations, effective February 11, 1974 (39 FR 3756; Anonymous, 1974). Realization of the potential hazard of BCME grew dramatically when it was reported that at high concentrations, vapors of HCl and formaldehyde, two commonly used chemicals in many industries and laboratories, can combine spontaneously to form BCME.

The concern over BCEE and BCIE arose mainly because of their presence in river water and the drinking water of several U.S. cities. These chemicals were found at high concentrations in waste water from chemical plants involved in the manufacturing of glycol products, rubber, and insecticides. As an end product, BCEE is an excellent solvent for fats, waxes, and greases. It can be used as a scouring agent for textiles and has also been employed as an insecticide, ascaricide, and soil fumigant. The U.S. EPA has included these two compounds in its National Organics Monitoring Survey (NOMS) of U.S. drinking water (U.S. EPA, 1977).

EXPOSURE

Ingestion from Water

Chloroalkyl ethers do not occur as such in nature; their occurrence is entirely anthropogenic. Discharges from industrial and manufacturing processes represent the major sources of these organic pollutants in the aquatic environment. Chlorination of drinking water could also be a potential source.

The stability of chloroalkyl ethers in aqueous systems plays a crucial role in determining their persistence in the water. In general, α -chloroalkyl ethers have an extremely short lifetime in aqueous solutions and are therefore not expected to persist for any extended period of time in water. On the other hand, other chloroalkyl ethers are quite stable and may persist in the aqueous

environment. The rate of hydrolysis of a number of α -chloroalkyl ethers in an aqueous system has been measured by Van Duuren, et al. (1972). In a solution of water-dimethylformamide (3:1) kept at 0°C, the four α -chloroalkyl ethers (BCME, CMME, bis(α -chloroethyl) ether, α, α -dichloromethylmethyl ether) tested were found to have a rate constant greater than 0.35 min^{-1} with a half-life of less than two minutes. Kinetic studies of BCME hydrolysis by Tou and coworkers confirmed the above finding. In neutral aqueous solution, the $t_{1/2}$ was 280, 38, and 7 seconds at 0°C, 20°C, and 40°C, respectively. The hydrolysis was faster in alkaline solution and slower in acidic solution (Tou, et al. 1974). A comparably fast rate of hydrolysis of BCME was observed in aqueous solutions containing hydrochloric acid and formaldehyde (Tou and Kallos, 1974a) or anion-exchange resins (Tou, et al. 1975). CMME is even more reactive than BCME. Its half-life in aqueous solution cannot be directly measured with accuracy. Jones and Thornton (1967) have measured the hydrolysis rate of CMME in aqueous isopropanol. Extrapolation of the data to pure water yielded a $t_{1/2}$ of less than one second (Tou and Kallos, 1974b). In aqueous methanol at 45°C, the hydrolysis rate of CMME was about 5,000 times faster than that of BCME (Nichols and Merritt, 1973).

In contrast to α -chloroalkyl ethers, the β -chloro compounds are much more stable. Van Duuren, et al. (1972) found that the half-life of BCEE was more than 23 hours in water-dimethylformamide (3:1) at 30°C. Bohme and Sell (1948) estimated the half-life of BCEE to be 12.8 days in a mixture of water-dioxane solution at 100°C. Kleopfer and Fairless (1972) observed that BCIE appeared to

be quite persistent in contaminated river water; there was no sign of biodegradation.

The occurrence of chloroalkyl ethers in river water and finished drinking water has been reported by various investigators. Among the chloroalkyl ethers covered in this document, BCEE and BCIE have been consistently detected in some areas of the country and quantitatively determined in some cases. Shackelford and Keith (1976) have recently compiled information on the frequency of organic compounds identified in water from published literature and unpublished survey analyses from U.S. EPA laboratories. Occurrence of BCEE and BCIE in various types of water, has been reported 10 and 19 times, respectively. Other chloroalkyl ethers, occasionally reported, included BCEXM, BCEXE, vinyl 2-chloroethyl ether, 2-chloroethyl methyl ether, BCME, and chloromethyl ethyl ether. In view of the extremely short lifetime of α -chloroalkyl ethers in aqueous systems, reports of their presence in water are probably erroneous. Schulting and Wils (1977) have noted that even the sophisticated GC-MS selected ion monitoring (SIM) method may yield false results. Using SIM on a SE-30 column, the authors demonstrated that 1-chloro-2-propanol could be mistaken for BCME. Reports of occurrence of β -chloroalkyl ethers in water appear to be more reliable and in some cases quantified; the major findings of these reports are summarized in Table 3.

Rosen, et al. (1963) were the first to detect BCEE and BCIE in contaminated river water. Investigation of the cause of odor of the Kanawha River at Nitro, West Virginia, led to the qualitative identification of BCEE and BCIE as two of the pollutants. The

threshold odor concentrations for BCEE and BCIE were estimated to be 360 µg/l and 200 µg/l, respectively.

The presence of BCIE in river water and finished drinking water at Evansville, Indiana, was noted by Kleopfer and Fairless (1972). An industrial outfall, located about 150 river miles upstream from the Evansville water intake, was found to be the probable source of the pollutant. Samples from this outfall were analyzed using flame-ionization and electron-capture detection gas chromatography, verified by IR and mass spectrometry, on several occasions during the fall of 1971. In each case BCIE was found in concentrations ranging from 0.5 to 35 mg/l; the estimated discharge was 68 kg/day. Concentrations of BCIE found in the Ohio River at Evansville ranged from 0.5 to 5.0 µg/l. The conventional drinking water treatment was capable of removing only 60 percent of BCIE from the raw river water. BCIE concentration of 0.8 µg/l was found in the finished drinking water.

The detection of BCEE and BCEXM in the treated effluent from synthetic rubber plants was reported by Webb, et al. (1973); the concentrations were on the order of 0.16 mg/l and 140 mg/l, respectively. BCIE was also readily detected in a thickening and sedimentation pond of glycol plants.

The lower region of the Mississippi River is well known for being heavily contaminated with organic pollutants from industrial discharges. Since 1969, the drinking water of the New Orleans area has been closely monitored by the U.S. EPA with detection of various pollutants frequently reported. Keith, et al. (1976) have recently compiled detailed quantitative data from these studies.

At the Carrollton station and two sites in Jefferson Parish, the finished drinking water was found to contain BCEE at levels of 0.04, 0.16, and 0.12 $\mu\text{g}/\text{l}$, respectively. The corresponding values for BCIE were 0.18, 0.08, and 0.03 $\mu\text{g}/\text{l}$.

In a report to Congress, the U.S. EPA (1975) summarized the findings of organics in U.S. drinking water. A number of chloroalkyl ethers were detected, with the highest reported concentrations for BCEE, BCIE, and BCEXE being 0.42 $\mu\text{g}/\text{l}$, 1.58 $\mu\text{g}/\text{l}$, and 0.03 $\mu\text{g}/\text{l}$, respectively. In a study of 10 cities, the drinking water of Philadelphia was found to contain 0.5 $\mu\text{g}/\text{l}$ BCEE and 0.03 $\mu\text{g}/\text{l}$ BCEXE. The drinking water of the other nine cities did not contain these chloroalkyl ethers (U.S. EPA, 1975).

The discovery of BCEE in Philadelphia's drinking water initiated a flurry of activity to determine the source and find means of elimination (Manwaring, et al. 1977). A chemical manufacturing plant located near the city's water intake admitted that it had discharged approximately 61.4 kg/day of the compound into the river (Anonymous, 1975). The effluent from the chemical plant contained up to 41 $\mu\text{g}/\text{l}$ BCEE. Samples of the river adjacent to the discharges showed the presence of up to 10 $\mu\text{g}/\text{l}$ of the chemical. Between February and July of 1975, the city's finished drinking water contained BCEE ranging from 0.04 to 0.6 $\mu\text{g}/\text{l}$. The chemical company has since developed a BCEE destruction system for the treatment of its effluent, and this system resulted in a greater than 99 percent reduction in the discharge of BCEE into the river (Manwaring, et al. 1977). In a more recent survey by Sheldon and Hites (1978), BCEE was barely detectable (~ 0.01 $\mu\text{g}/\text{l}$) in the river water.

However, a high concentration of another chloroalkyl ether (BCEXE (15 µg/l)) was detected in two of the five samples examined.

A National Organics Monitoring Survey of the U.S. drinking water has recently been undertaken by U.S. EPA (1977). Three phases of the study were carried out in March-April 1976, May-July 1976, and November 1976-January 1977. The drinking water of 113 cities has been analyzed for organic pollutants, including chloroalkyl ethers. In phase I, BCEE was not found in 112 cities at the minimum quantifiable limit of 5 µg/l. In phases II and III, the limit was lowered to 0.01 µg/l. In phase II, the drinking water of 13 of the 113 cities was found to contain BCEE, with a mean concentration of 0.10 µg/l. BCIE was also found in 8 of the 113 cities. The quantitative data of the phase II study have been published by Dressman, et al. (1977) and are summarized in Table 4. In phase III, 8 of 110 (7.27 percent) cities had BCEE, with a mean of 0.024 µg/l. For BCIE, 7 of 110 (6.36 percent) cities gave positive results, with a mean of 0.11 µg/l (U.S. EPA, 1977).

BCME can be chemically produced by saturating a solution of paraformaldehyde in cold sulfuric acid with HCl. Van Duuren, et al. (1969) studied the reaction of BCME with deuterium oxide in dioxane. Rapid disappearance of BCME was observed, with 70 percent of the compound hydrolyzed within two minutes. However, after 18 hours, about 20 percent of BCME was still present. This suggested a possible equilibrium between BCME and its hydrolysis products, HCl and formaldehyde, and further raised the question of whether BCME could be formed spontaneously from HCl and formaldehyde. This question received great attention when the Rohm and Haas Company

disclosed that BCME could be detected in humid air and aqueous or nonaqueous liquid-phase systems containing high concentrations of HCl and formaldehyde (Anonymous, 1972). However, more recent studies by Tou and Kallos (1974a, 1976) have indicated that, at least for aqueous systems, there was no evidence of BCME formation from HCl and formaldehyde at a detection limit of an order of magnitude of parts per trillion.

Ingestion from Food

There is no information on the possible human exposure to chloroalkyl ethers via ingestion of food. The levels of chloroalkyl ethers in food have not been monitored, nor has there been any attempt to study the bioaccumulation of chloroalkyl ethers. However, in view of their relative stability and low water solubility, β -chloroalkyl ethers may have a high tendency to be bioaccumulated.

Neely, et al. (1974) have noted a linear correlation between the octanol/water coefficients (P_{octanol}) and bioconcentration factors of chemicals in trout muscle. The relationship can be expressed by the equation:

$$\text{Log (bioconcentration factor)} = 0.542 \text{ log } (P_{\text{octanol}}) + 0.124.$$

The P_{octanol} for chloroalkyl ethers is not available. However, Suffet and Radziul (1976) have published partition coefficients of BCEE in a number of other organic solvents. Ether was the most extensively used solvent; the average P_{ether} calculated from their data was 8.35. Using the solvent regression equation of Leo, et al. (1971), P_{ether} may be converted to P_{octanol} by employing the formula:

$$\text{Log } (P_{\text{ether}}) = 1.142 \text{ log } (P_{\text{octanol}}) - 1.070.$$

From these data, it can be calculated that the bioconcentration factor of BCEE in trout muscle should be around 11.7.

The P_{octanol} of chloroalkyl ethers may also be calculated based on their solubility in water according to the method outlined by Chiou and Freed (1977). Using the above method, the information on water solubility of chloroalkyl ethers (Durkin, et al. 1975), and the linear regression model (Neely, et al. 1974), the extrapolated bioconcentration factors for BCEE, BCIE and 2-chloroethyl vinyl ether are 12.6, 56.2, and 34.2, respectively.

Another approach to calculating bioconcentration factors has been recommended by the U.S. EPA's ecological laboratory in Duluth, Minnesota. This approach states that a bioconcentration factor (BCF) relates the concentration of a chemical in aquatic animals to the concentration in the water in which they live. The steady-state BCFs for a lipid-soluble compound in the tissues of various aquatic animals seem to be proportional to the percent lipid in the tissue. The per capita ingestion of a lipid-soluble chemical can be estimated from the per capita consumption of fish and shellfish, the weighted average percent lipids of consumed fish and shellfish, and a steady-state BCF for the chemical.

Data from a recent survey on fish and shellfish consumption in the United States were analyzed by SRI International (U.S. EPA, 1980). These data were used to estimate that the per capita consumption of freshwater and estuarine fish and shellfish in the United States is 6.5 g/day (Stephan, 1980). In addition, these data were used with data on the fat content of the edible portion of

the same species to estimate that the weighted average percent lipids for consumed freshwater and estuarine fish and shellfish is 3.0 percent.

A measured steady-state bioconcentration factor of 11 was obtained for bis(2-chloroethyl)ether using bluegills (U.S. EPA, 1978). Similar bluegills contained an average of 4.8 percent lipids (Johnson, 1980). An adjustment factor of $3.0/4.8 = 0.625$ can be used to adjust the measured BCF from the 4.8 percent lipids of the bluegill to the 3.0 percent lipids that is the weighted average for consumed fish and shellfish. Thus, the weighted average bioconcentration factor for bis(2-chloroethyl)ether and the edible portion of all freshwater and estuarine aquatic organisms consumed by Americans is calculated to be $11 \times 0.625 = 6.9$.

No measured steady-state bioconcentration factor is available for bis(chloromethyl)ether, 2-chloroethylvinyl ether, bis(2-chloroisopropyl)ether, or bis(2-chloroethoxy)methane, but the equation " $\text{Log BCF} = (0.85 \text{ Log } P) - 0.70$ " can be used (Veith, et al. 1979) to estimate the BCF for aquatic organisms that contain about 7.6 percent lipids (Veith, 1980) from the octanol/water partition coefficient (P). Since no measured log P values could be found, log P values of 1.06, 1.00, 1.76, and 1.07 were calculated for bis(chloromethyl)ether, 2-chloroethylvinyl ether, bis(2-chloroisopropyl)ether, and bis(2-chloroethoxy)methane using the method described in Hansch and Leo (1979). The steady-state bioconcentration factors are estimated to be 1.59, 1.41, 6.25, and 1.62, respectively. An adjustment factor of $3.0/7.6 = 0.395$ can be used to adjust the estimated BCF from the 7.6 percent lipids on which the

equation is based to the 3.0 percent lipids that is the weighted average for consumed fish and shellfish. Thus, the weighted average bioconcentration factors for bis(2-chloromethyl)ether, 2-chloroethylvinyl ether, bis(2-chloroisopropyl)-ether and bis-(2-chloroethoxy)methane and the edible portion of all freshwater and estuarine aquatic organisms consumed by Americans are calculated to be 0.628, 0.557, 2.47, and 0.64, respectively.

The use of aquatic organisms as a typical exposure factor requires the quantification of pollutant residues in the edible portion of the ingested species. For this reason, the U.S. EPA-recommended calculations, based upon the percent lipids of aquatic organisms, were used in the formulation of the criterion.

Inhalation

There is no evidence of occurrence of chloroalkyl ethers in the atmosphere. Human exposure to compounds via inhalation appears to be confined to occupational settings. It is important to note that, in contrast to its instability in aqueous solution, BCME is considerably more stable in humid air. Frankel, et al. (1974) found that BCME introduced into a Saran[®] bag containing moist air was stable for at least 18 hours. Tou and Kallos (1974b) have studied the stability of BCME and CMME in humid air. At an ambient temperature with a relative humidity of 81 percent, the $t_{1/2}$ of BCME in the gaseous phase could be as long as 25 hours. The rate of hydrolysis was dependent on the surface of the container. In a ferric oxide-coated Saran[®] reactor, the $t_{1/2}$ of BCME was on the order of seven to nine hours. A similar surface effect on the

hydrolysis of CMME in the gaseous phase was also observed. The $t_{1/2}$ of CMME in the gaseous phase ranged from 2.3 minutes to 6.5 hours.

The extreme potency of BCME and/or CMME as inhalation carcinogens has prompted industrial hygienists and researchers to closely monitor the atmospheric level of these compounds in the work place. Various such methods have been developed (e.g., Collier, 1972; Solomon and Kallos, 1975; Sawicki, et al. 1976; Parkes, et al. 1976; Kallos, et al. 1977; Bruner, et al. 1978). The finding of spontaneous formation of BCME from HCl and formaldehyde vapors has expanded the potential sites of BCME exposure to any place where high atmospheric levels of these two reactants may co-exist. Rohm and Haas Company first disclosed information on the spontaneous formation of BCME from HCl and formaldehyde (Anonymous, 1972). At room temperature of about 71°F and with a 40 percent relative humidity, a steady state level of BCME could be reached within one minute. In general, ppm levels of the reactants yielded ppb levels of BCME. This important finding has since been confirmed; however, the yield in such a reaction is much lower than was previously anticipated. Frankel, et al. (1974) reported that at 25°C and 40 percent relative humidity, fewer than 0.5 ppb of BCME was formed from 20 ppm each of HCl and formaldehyde. At 100 ppm or 300 ppm of each reactant, the average yield was 2.7 or 23 ppb BCME, respectively. The factors that affect the yield included the reactant concentration, the surface of the reactor, the reaction time, the humidity and temperature. A substantially lower yield was observed by Kallos and Solomon (1973). At 100 ppm of each of the reactants, only 0.1 ppb BCME was detected. Nevertheless, with high concentrations

of the reactants, substantial amounts of BCME could be detected. The National Institute for Occupational Safety and Health (NIOSH) is currently investigating the possible formation of BCME in various work places where HCl and formaldehyde may be used simultaneously (Lemen, et al. 1976).

In addition to HCl and formaldehyde, a number of other chemicals are potential reactants for the formation of BCME. Gamble (1977) reported that BCME could be detected in an animal room that had been washed with a 15 percent hypochlorite solution followed by routine gassing with formaldehyde. Duplicate air samples were taken from both high levels (3 m) and low levels (1 m). No BCME was detected in the high-level sample whereas 0.2 ppb of BCME was found in the low-level sample. The author recommended that chlorine-containing disinfectants should not be used when animal rooms are gassed with formaldehyde. Another possible source of BCME in the work place was suspected to be from the reaction of dimethyl ether and chlorine in air. Kallos and Tou (1977) have investigated this possibility. The reaction was found to be photochemical in nature. In ambient air BCME was barely detectable; the highest amount detected was 2 ppb from 100 ppm each of chlorine and dimethyl ether. However, it is interesting to note that as much as 1.5 ppm BCME was found to be generated during the reaction of 100 ppm of each of the reactants in dry nitrogen.

Dermal

There was no information available on the dermal exposure of humans to chloroalkyl ethers; no evaluations can be made regarding the relative importance of dermal exposure. One potential source

of dermal exposure has, however, been investigated by Loewengart and Van Duuren (1977). Tetra-bis(hydroxymethyl)phosphonium chloride (THPC), a widely used flame retardant in children's sleepwear, is synthesized from phosphine, hydrochloric acid, and formaldehyde and may decompose thermally or chemically to these chemicals. Thus, THPC is also a potential source of BCME reactants under the right conditions. Because of the high add-on (up to 35 percent of the final fabric weight) of the flame retardant, it seems likely that a fraction of THPC may be loosely bound and that common solutions such as sweat, urine, and saliva may be able to extract some free THPC. A sample of commercial THPC was found to contain 4 to 14 percent (w/w) free formaldehyde. Gas chromatographic analysis of aqueous commercial THPC did not reveal any peak characteristic of BCME; however, the limit of detection of the study was only 0.1 ppm. THPC is also marginally active as a skin carcinogen and active as a tumor promotor (Loewengart and Van Duuren, 1977).

PHARMACOKINETICS

No information is available on the pharmacokinetics of chloroalkyl ethers in humans; animal data are also rather scanty. The α -chloroalkyl ethers, by virtue of their high reactivity and short lifetime in aqueous systems, are not expected to persist in

the body. Nonetheless, Gargus, et al. (1969) observed a significant increase in the incidence of lung tumors after s.c. injection of BCME to newborn mice. This finding may indirectly indicate that BCME may be absorbed from the subcutaneous tissue and induce tumors at a site remote from the site of injection.

Smith, et al. (1977) have recently published detailed pharmacokinetic data on BCIE in female rats and monkeys. The BCIE was believed originally to be labeled with ^{14}C at the β -position. However, subsequently it was ascertained that labeling actually occurred in the α -position (Lingg, personal communication). After single oral doses, BCIE appeared to be readily absorbed by both species. In the monkey, the blood radioactivity level reached a high peak within two hours and then declined in a biphasic manner with a $t_{1/2}$ of about five hours and greater than two days for the first and second phases, respectively. In the rat, the blood radioactivity level reached a maximum between two and four hours after dosing and then slowly declined with a $t_{1/2}$ of two days. There was a substantial difference in the tissue distribution and excretion pattern seven days after a single parenteral dose of 30 mg/kg of ^{14}C -BCIE. The monkey retained substantially higher amounts of radioactivity in the liver (equivalent to 28.8 $\mu\text{g/g}$ BCIE) than did the rat (3.2 $\mu\text{g/g}$). Higher quantities were also found in the muscle and brain of the monkey. On the other hand, with respect to the percentage of administered dose recovered in the tissues and excreta, higher amounts of radioactivity were found in the fat (1.98 percent), urine (63.36 percent), feces (5.87 percent), and expired air (15.96 percent) of the rat. The corresponding figures in the

monkey were 0.78 percent, 28.61 percent, 1.19 percent, and 0 percent. Metabolites of BCIE in the rat included 1-chloro-2 propanol, propylene oxide, 2-(1-methyl-2-chloroethoxy)-propionic acid and carbon dioxide. Initial attempts to analyze the urinary metabolites of BCIE in the monkey had been inconclusive because of the presence of interfering substances.

The fate of BCEE in rats after acute oral administration has been studied by Lingg, et al. (1978). Bis((1-¹⁴C)chloroethyl)-ether (40 mg/kg) was administered to male Sprague-Dawley rats by intubation. Preliminary results showed that virtually all of the BCEE was excreted as urinary metabolites with more than 60 percent of the compound excreted within 24 hours. One major metabolite was thiodiglycolic acid. A lesser metabolite was identified as 2-chloroethanol- β -D-glucuronide. The presence of these two metabolites suggests that cleavage of the ether linkage is a major step in the biotransformation of BCEE. The products of this cleavage then conjugate with nonprotein-free sulfhydryl groups or with glucuronic acid, with the former as the major route of conjugation in the rat.

The metabolic fate of other chloroalkyl ethers is not known. However, it is interesting to note that cleavage of the ether linkage also appears to be a route of metabolism for diethyl ether in mice (Geddes, 1971). For p-dioxane, a cyclic ether, ring hydroxylation has been postulated as the first step of metabolism in the rat (Woo, et al. 1977). The major urinary metabolite has been identified as 2-hydroxyethoxyacetic acid (Braun and Young, 1977) or

p-dioxane-2-one (Woo, et al. 1977) which are readily interconvertible depending on the pH of the system.

EFFECTS

Acute, Subacute, and Chronic Toxicity

Animal Studies: The acute toxicity of a variety of chloroalkyl ethers has been studied in different animal species. Tables 5 and 6 summarize the acute toxicity data. It is apparent from Table 5 that the route of exposure may play a determining factor in the acute toxicity of chloroalkyl ethers. In the rat, the inhalational toxicity follows the order, BCME > CMME > BCEE > BCIE; by oral administration, however, the order is changed to BCEE > BCIE > BCME > CMME. Apparently, the extremely short lifetime of BCME and CMME in aqueous solution significantly reduces their toxic potential by oral administration. It is also of interest to note the dramatic enhancement of toxicity of p-dioxane after chlorination. The acute LD₅₀ of p-dioxane has been reported as 5.3 g/kg (Woo, et al. 1978). Chlorination of p-dioxane increases the toxicity by 10- to 1,000-fold. The stereochemistry of the compound also plays a significant role; the 2r,3t,5t,6c-tetrachloro isomer was found to be 80 times more toxic than its 2r,3c,5t,6t-stereoisomer (Woo, et al. 1979).

The acute physiological response of the guinea pig to air containing toxic concentrations of BCEE has been studied by Schrenk, et al. (1933). The primary action was the irritation of the respiratory passages and the lungs. In the order of their appearance, the symptoms produced were nasal irritation, eye irritation, lacrimation, disturbances in respiration, dyspnea, gasping, and death.

The principal gross pathology findings were congestion, emphysema, edema, and hemorrhage of the lungs.

Gage (1970) exposed rats to eight, 5-hour exposures of 350 ppm BCIE in air; the toxic sign observed included respiratory difficulty, lethargy, and retarded weight gain. Histological examination of liver and kidneys revealed signs of congestion. Lethargy and retarded weight gain were also observed in a group exposed 20 times, six hours each, to 70 ppm of BCIE in air. The highest concentration with no toxic signs was 20 ppm.

The National Cancer Institute (NCI) unpublished results of a recently completed chronic toxicity study of BCIE has been summarized according to the observations of nontumor pathology in Table 7. The most significant change in the mouse appeared to be an increased incidence of centrilobular necrosis of the liver. However, the effect was inexplicably higher in the low-dose group than in the high-dose group. In the rat, the major effect of BCIE was on the lungs, causing congestion, pneumonia, and aspiration.

A detailed study of the inhalational toxicity of BCME and CMME has recently been carried out by Drew, et al. (1975) with Sprague-Dawley rats and Syrian golden hamsters as the test species. The most characteristic acute toxic effect of both compounds was the irritation of the respiratory tract manifested by congestion, edema, and hemorrhage (mainly of the lungs) and acute necrotizing bronchitis. The lung-to-body weight ratios, which were used as an objective criterion for the evaluation of lung damage, in animals exposed to CMME were elevated in a dose-related fashion. Multiple exposures of animals to subacutely toxic concentrations of BCME or

*Animals dosed 5 days/week for total of 728 days.

CMME resulted in severe shortening of lifespan and a variety of regenerative, hyperplastic, and metaplastic alterations of trachea and bronchi, which were often histopathologically atypical (such as nuclear abnormality). Incidences of mucosal changes were generally increased in a dose-related manner in both species. Similar changes were observed in studies of the long-term effects of single exposure to BCME or CMME. For animals surviving beyond the median life span, pathological alterations of respiratory epithelium, abnormality of alveolar lining cells, and bronchoalveolar squamous metaplasia were also occasionally noted.

Human Studies: The effect of brief exposures of man to BCEE vapor was studied by Schrenk, et al. (1933). Concentrations of greater than 260 ppm were found to be very irritating to the nasal passages and eyes with profuse lacrimation. Deep inhalations were nauseating in effect. The highest concentration with no noticeable sign of irritation was 35 ppm. For comparison, BCME was reported (Flury and Zernik, 1931, cited in Schrenk, et al. 1933) to be distinctly irritating at a concentration of 3 ppm. A concentration of 100 ppm would incapacitate a person under chemical warfare conditions in a few seconds, and an exposure of 1 to 2 minutes might produce a fatal lung injury. A fatal case of accidental, acute poisoning of a research chemist by BCME has been reported (Thiess, et al. 1973).

The respiratory effects of chronic exposures of industrial workers to CMME (contaminated with BCME) have been extensively investigated by Weiss and coworkers. Symptoms of chronic bronchitis were noted more often among exposed men, and a dose-response

relationship was apparent with smoking as a cofactor. There was no demonstrable chemical effect on the ventilatory function, as measured by the forced vital capacity (FVC) and the 1-second forced expiratory volume (FEV_1), suggesting the absence of abnormality in the large airways (Weiss and Boucot, 1975). The small airways were, however, noticeably affected by the chemical exposure. The end-expiratory flow rate (EEFR) was below 60 percent of the predicted value in one-third of the exposed men compared to only three percent of the unexposed men. There was a dose-response relationship between chemical exposure and the frequency of low EEFR (Weiss, 1977).

Synergism and/or Antagonism

There is very little information available on the synergistic or antagonistic interaction of chloroalkyl ethers with other types of chemical carcinogens in experimental animals. Promotion of tumorigenesis after initiation by chloroalkyl ethers has, however, been extensively studied. In two-stage mouse skin carcinogenesis studies, the following compounds have been considered as "incomplete" carcinogens (i.e., active only as "initiators"): CMME, octachlorodi-n-propyl ether, and α,α -dichloromethyl ether (Van Duuren, et al. 1969, 1972). Induction of papillomas was also observed after promotion of the initiation by BCEE, bis(α -chloroethyl)-ether, or 2,3-dichlorotetrahydrofuran; whether these compounds are "complete" carcinogens or not is not known (Van Duuren, et al. 1972). Chloroalkyl ethers capable of inducing papillomas or carcinomas on mouse skin without promotion include BCME (Van Duuren, et al. 1969) and 2,3-trans-dichloro-p-dioxane (Van Duuren, et al.

1974); the carcinogenic activity of these compounds can be substantially enhanced by promoters (Van Duuren, 1969; Van Duuren, et al. 1969, 1974; Slaga, et al. 1973). The details of these carcinogenicity data will be presented in the Carcinogenicity section. The promoters used included croton oil, croton resin, or the pure phorbol myristate acetate. The tumor-promoting activity of several chloroalkyl ethers has been tested using benzo(a)pyrene as the initiator. BCME was found to decrease the latent period for induction of benign and malignant tumors but did not affect the tumor yield (Van Duuren, et al. 1968, 1969). CMME and octachlorodi-n-propyl ether were marginally active as promoters (Van Duuren, et al. 1969).

The ability of chloro derivatives of p-dioxane to modify microsomal drug-metabolizing enzyme activity has been studied by Woo, et al. (1979). Of the compounds tested (listed in Table 6), only 2r,3c,5t,6t-tetrachloro-p-dioxane was found to have a significant effect. The activities of microsomal aryl hydrocarbon hydroxylase and dimethylnitrosamine-demethylase were decreased by 44 percent and 61 percent, respectively.

Cigarette smoking has been found to act synergistically with CMME to produce chronic bronchitis and small airway disorders among exposed industrial workers (Weiss and Boucot, 1975; Weiss, 1976, 1977). In sharp contrast, however, there was an unexpected inverse relationship between smoking and the induction of lung cancer by CMME (Weiss and Boucot, 1975; Weiss, 1976). The reason for this apparent antagonism is not known. Self-selection by the workers has been suggested as a possible factor. Heavy cigarette smokers

might have tended to avoid heavy chemical exposure because chronic cough was directly related to both CMME exposure and cigarette smoking, and simultaneous exposure might produce a greater effect than either one alone. However, no data on smoking habit changes were available to verify the self-selection hypothesis. Another possible factor was the protective action of bronchorrhea associated with chronic bronchitis. The excessive discharge from bronchial mucous membrane may protect against the carcinogenic effect of CMME or its contaminant BCME by reducing the residence time of these chemicals because of their instability in aqueous systems. Finally, it is conceivable that some component of cigarette smoke may neutralize the carcinogenicity of CMME. It is not known whether the apparent antagonism observed by Weiss may be a general phenomenon. In reviewing the case reports of four different groups of workers, Lemen, et al. (1976) expressed the view that smoking may provide a promotional or synergistic effect on the induction of lung cancer by BCME.

Teratogenicity

The teratogenicity of the chloroalkyl ethers covered in this document has not been studied. It is relevant to note, however, that there is some epidemiological evidence that anesthetic gases (including methoxyflurane) may lead to congenital abnormalities. Although the evidence has been considered less than unequivocal, there is little doubt that these gases are teratogenic in experimental animals when administered in relatively high doses (Smith, 1974; Corbett, 1976; Ferstandig, 1978). A detailed discussion of this subject is beyond the scope of this document. However, in

view of the fact that methoxyflurane can actually be classified as a chloroalkyl ether, the teratogenicity of other chloroalkyl ethers (especially the environmentally important and stable BCEE and BCIE) should be critically studied.

methoxyflurane

Mutagenicity

The mutagenicity of chloroalkyl ethers has been investigated in bacterial, eukaryotic, and mammalian systems. Table 8 compares the carcinogenicity data to the mutagenicity data in microbial systems for a variety of chloroalkyl ethers. With a few exceptions, there is a relatively good correlation between mutagenicity and carcinogenicity. For most of these studies, E. coli and S. typhimurium were used as the test organisms, and the test was designed for direct-acting mutagens that do not require metabolic activation.

There are some disagreements regarding the mutagenicity of BCEE. Shirasu, et al. (1975) have found BCEE to be a direct-acting, base-change mutagen using different tester strains of E. coli, S. typhimurium, and B. subtilis. It was also reported by Fishbein (1977) that BCEE, when tested in a desiccator containing the vapor, was mutagenic to S. typhimurium strains TA 1535 and TA 100 and weakly mutagenic to strains TA 1538, TA 98, and E. coli WP2. In suspension assays, BCEE also proved to be mutagenic toward strain TA 1535. BCEE was not mutagenic in host-mediated assays

^aThe mutagenicity data were mainly reported by Nelson, 1976.

^bPositive mutagenic activity of BCEE was observed by Shirasu, et al. 1975, and the mutagenicity of BCEE and BCIE were reported in Fishbein, 1977.

when given as a single oral dose or when administered for two weeks prior to the injection of S. typhimurium into the peritoneal cavity.

In eukaryotic and nonmammalian systems, BCEE was reported to be mutagenic to Saccharomyces cerevisiae D3 in suspension assay (Fishbein, 1977). BCEE has been quoted as mutagenic to Drosophila melanogaster (Fishbein, 1976, 1977); however, a careful examination of the original publication of Auerbach, et al. (1947) failed to confirm the quotation. It was bis-(2-chloroethylmercaptoethyl) ether (not BCEE) that was mutagenic.

The mutagenic potential of BCEE and BCIE in mice has been studied by Jorgenson, et al. (1977) using the heritable translocation test. Adult male mice were treated by gavage daily for three weeks with three dose levels of BCEE or BCIE. They were then mated to virgin females to produce an F₁ generation. The F₁ males were bred twice and examined cytogenetically. Preliminary evaluation of the breeding and cytogenetic data suggests that BCEE and BCIE were not mutagenic; no heritable translocations were observed.

The genetic risks of occupational exposures to CMME and BCME have been evaluated by Zudova and Landa (1977). Cytogenetic analysis of peripheral lymphocytes was performed. Scoring 200 cells per person, the authors detected 6.7 percent of aberrant cells in exposed workers while the corresponding value in the controls reached only 2 percent. The frequency of aberrant cells in exposed workers decreased toward the control value after the removal of exposure. It was proposed that cytogenetic analysis of peripheral lymphocytes

should become a part of a routine medical check-up of workers at risk.

Carcinogenicity

Animal Studies: Van Duuren, et al. (1968) were the first to demonstrate the carcinogenicity of chloroalkyl ethers. Application of 2 mg BCME three times a week for 325 days led to the induction of papillomas in 13/20 mice, 12 of which developed to squamous cell carcinomas. A comparison with a number of other carcinogenic alkylating agents (Table 9) indicated that BCME was, for the mouse skin, more potent than the β -lactones and epoxides listed in terms of tumor yield, dose, and latency. In contrast, CMME was found to be inactive as a complete carcinogen by skin application.

In an effort to delineate the structure-activity relationships of chloroalkyl ethers, Van Duuren and coworkers have extended their cutaneous carcinogenicity studies to a variety of compounds. The test procedures used included s.c. injection in mice, repeated direct application to mouse skin, and tests in mice by the initiation-promotion procedure involving a single application of the test compound followed by repeated applications of phorbol myristate acetate. Table 10 summarizes the results of this extensive series of studies. By skin application, BCME, trans-2,3-dichloro-p-dioxane, bis-1,2-(chloromethoxy)ethane, and tris-1,2,3-(chloromethoxy) propane were found to be active as complete carcinogens. Most of the other compounds tested were active as initiators. From these studies, three salient features of structure-activity relationships were observed. (1) The bifunctional α -chloroalkyl ethers (e.g., BCME) are more active than their monofunctional analogs

(e.g., CMME). (2) The carcinogenic activity of chloroalkyl ether decreases as chlorine moves further away from the ether oxygen. Thus, β -chloroalkyl ethers (e.g., BCEE) are substantially less active than their α -chloro isomers or analogs (e.g., bis(α -chloroethyl)ether). (3) The carcinogenic activity decreases as the alkyl chain length increases. For example, if one considers BCME, bis-1,2-(chloromethoxy)ethane, bis-1,4-(chloromethoxy)butane, and bis-1,6-(chloromethoxy)hexane as a homologous series of di- α -chloro ethers of increasing length, it is clear that in general, the longer the chain length, the lower the carcinogenicity.

The carcinogenicity of BCME and CMME in newborn ICR Swiss random bred mice has been tested by Gargus, et al. (1969) by s.c. injection. A single dose of 12.5 μ l BCME/kg body weight was found to increase the pulmonary tumor incidence after six months. In 50 males and 50 females injected with BCME, pulmonary tumors developed in 45 percent of the animals, with a multiplicity of 0.64 tumors per mouse. In addition, one mouse developed an injection site papilloma and another a fibrosarcoma; such tumors were not seen in control animals. In the vehicle (peanut oil) controls, the pulmonary tumor incidence was 14 percent with a multiplicity of 0.14. Mice receiving CMME (125 μ l/kg) had an incidence of 17 percent with a multiplicity of 0.21; these values were slightly higher but not significantly different from the controls. It is of particular interest to point out the high carcinogenic potency of BCME in this study. A single, very small dose of 12.5 μ l (equivalent to 0.017 mg/kg) was sufficient to induce pulmonary adenomas within six months. Furthermore, this study indicated that, despite its short

lifetime in an aqueous system, the biological effects of BCME were not confined to the site of injection. On the other hand, using rats, s.c. injection of BCME produced no increase in the incidence of tumors remote from the injection site (Van Duuren, et al. 1969).

The tumor initiating ability of BCME and CMME has also been studied by Slaga, et al. (1973) using female Charles River CD1 mice. A single dose of 9 μ moles (1.03 mg) BCME was sufficient to induce papillomas within 15 weeks after promotion by croton oil. CMME, up to a dose of 25 μ moles (2.0 mg), was found to be a very weak or inactive initiating agent.

The high vapor pressure of CMME (b.p. 59°C) and BCME (b.p. 104°C) at ambient temperatures and their extensive industrial uses have prompted investigators to examine the inhalational carcinogenicity of these compounds. Leong, et al. (1971) were the first to test the inhalational carcinogenicity of BCME and CMME in mice. Strain A/Heston male mice, which are known to be highly responsive to pulmonary tumor induction with a spontaneous incidence of about 40 percent were used in this study. The animals were exposed six hours/day, five days/week to filtered room air (negative control), aerosols of urethane (positive control), or vapors of BCME or CMME for up to a maximum of six months. The CMME used contained 0.3 to 2.6 percent BCME as an impurity. The animals were sacrificed at the end of the six-month period (Table 11 summarizes the results). Mice in the BCME exposed group had a 34 percent increase in the incidence of lung tumors and a 3.3-fold enhancement in the average number of tumors/animal/treatment group. The corresponding figures in the CMME exposed group were 21 percent and 1.75-fold. It was

*Source: Leong, et al. 1971

concluded that BCME was a potent inhalational carcinogen. CMME was also, for practical purposes, carcinogenic although it was not certain whether the effect was exerted by CMME itself or its contaminant, BCME.

An extensive series of inhalational carcinogenicity studies of BCME and CMME in rat and hamster has been carried out by Laskin, et al. (1971, 1975), Drew, et al. (1975), and Kuschner, et al. (1975). Table 12 summarizes the results of their findings. BCME was found to be an extremely potent respiratory carcinogen in the rat. Limited exposures (no more than 100 daily exposures of six hours each) of 200 rats to 0.1 ppm BCME led to the induction of respiratory cancers in 40 animals. The type of tumors induced and the time required for the induction are summarized in Table 13. Twenty-six rats had tumors of the nose with esthesioneuroepithelioma as the major histological type. Fourteen rats had tumors of the lung, 13 of them squamous cell carcinomas. The carcinogenic effect of BCME was clearly dependent on the number of exposures (see Table 14) showing an excellent dose-response. The exposure-response curve (probit vs. log dose) showed a sigmoid type of relationship, and a linear relationship was obtained by plotting log probit vs. log dose. The number of exposures at 0.1 ppm required to induce tumors in 50 percent of the rats was calculated to be 88. In experiments designed for subacute toxicity study, exposure of rats to 1 ppm BCME for three days (6 hours/day) led to the induction of squamous cell carcinoma of skin in 1 of the 50 animals. Syrian golden hamsters appeared to be very resistant to carcinogenesis by BCME. Lifetime exposure of hamsters to 0.1 ppm BCME resulted in only one

undifferentiated carcinoma of the lung in 1 of the 100 animals, whereas limited exposures (one or three exposures) brought about one tumor of the nose in one of each of the two groups of 50 animals.

The inhalational carcinogenicity of commercial grade CMME, which is usually contaminated with 1 to 7 percent BCME, has also been tested in rats and hamsters. Lifetime exposure to 1 ppm CMME led to the induction of one pulmonary and one nasal tumor in 74 exposed rats or two respiratory tumors in 90 exposed hamsters. Thus, in practical terms, commercial grade CMME must be considered as a respiratory carcinogen, although of a lower order of activity than BCME.

The carcinogenicity of BCEE by oral administration has been evaluated by Innes, et al. (1969); more recently, in view of its frequent occurrence in finished drinking water, further evaluations have been undertaken by Theiss, et al. (1977) and in the National Cancer Institute (Ulland, et al. 1973; Weisburger, personal communication). The major findings of these studies are summarized in Table 15. Two strains of mice of both sexes were used by Innes, et al. (1969). They received 100 mg/kg/day of BCEE for 80 weeks, first by intubation for three weeks followed by ingestion of food containing 300 ppm BCEE (estimated to be equivalent to daily intake of 100 mg/kg). The most significant finding was a substantially increased incidence of hepatoma, especially in male mice. The incidence of hepatomas in male and female controls of the strains were 8/79 and 0/87 in (C57BL/6X C3H/Anf)_F₁ mice and 5/90 and 1/82 in (C57BL/6XAKR)_F₁ mice. The incidence of hepatomas in male treated mice was significantly different from that in controls at the

$p = 0.01$ level. In contrast to the above study, Theiss, et al. (1977), using strain A mice (which have a high spontaneous pulmonary tumor incidence), were unable to detect any enhancement of pulmonary tumor incidence after repeated i.p. injections of BCEE. The average number of lung tumors/mouse was actually smaller in the treated group (0.11 to 0.15) than that in the tricapylin vehicle controls (0.39). In the study by the National Cancer Institute on the oral carcinogenicity of BCEE, Charles River CD rats of both sexes were used. Although detailed statistical analyses have not yet been completed, preliminary analyses suggest that BCEE did not cause any significant increase in the tumor incidence in the rat (Ulland, et al. 1973; Weisburger, personal communication).

The oral carcinogenicity of BCIE, another compound detected in the finished drinking water, has also been recently evaluated by the National Cancer Institute (NCI, unpublished). Mice of both sexes were intubated with BCIE at doses of 10 mg or 25 mg/kg/day, five days a week, for two years. Rats were similarly treated at doses of 100 or 200 mg/kg/day. The results of this study are summarized in Tables 16 and 17. Although these data have not yet been fully analyzed, they suggest that no marked increase in tumor incidence is induced by BCIE exposure.

The carcinogenicity of BCME and a number of other chloroalkyl ethers in mice by i.p. administration has been studied by Van Duuren, et al. (1974, 1975). The results are summarized in Table 18. In general, these compounds led to the induction of local tumors. However, papillary tumors of the lung were observed in 12 of the 30 animals treated with 2,3-trans-dichloro-p-dioxane.

Human Data: There is now sufficient epidemiological evidence to indicate unequivocally that BCME and, for practical purposes, CMME are human respiratory carcinogens. Including other important research, a total of at least 47 cases of respiratory cancer deaths in association with occupational exposure to these compounds has been observed (Nelson, 1976). A German report (Bettendorf, 1976) has placed the total figure at a minimum of 60 cases. Table 19 summarizes the published case reports of respiratory cancer deaths among exposed workers. These cases were observed in the United States, Germany, and Japan among exposed workers in the chemical manufacturing plants and laboratories. It is important to point out the relatively short latency for the induction of respiratory cancers by these chemicals. The latency period may be as short as eight years. Short durations of exposures may be sufficient to initiate carcinogenesis. Respiratory cancers occurred among cigarette smokers, cigar or pipe smokers, and ex-smokers as well as non-smokers. The average age of cancer death was around 42. The predominant histologic type of cancer was small-cell-undifferentiated carcinoma. The calculated increased risk factors of cancer due to chemical exposure are summarized in Table 20.

The five cases of lung cancer reported in Japan (Sakabe, 1973) occurred among 32 employees exposed to BCME and many other noxious chemicals in a dyestuff factory. Four of the workers exposed were involved in the synthesis of dyestuffs; the fifth case was exposed only in the laboratory. This represents a very high increased lung cancer risk.

TABLE 19

Case Reports of Respiratory Cancers Among Workers Exposed to DCME and/or CMME

Reference	No. of cases	Age at cancer exposure	Years of possible exposure	Induction -latency period (yr)	Working activity	Smoking habit	Histologic type of cancer

Reznik, et al. (1977)	1	45	2	12-13	Research chemist (Germany)	nonsmoker	adenocarcinoma

Thiess, et al. (1973) reported eight cases of respiratory cancer deaths in a chemical plant in Germany. Six of the cases occurred among 18 experimental technical department workers, a group known to experience very high exposures. In contrast, among the manufacturing workers, only two cases were observed among 50. Heavy exposures to BCME and CMME have been attributed as the cause of induction of lung adenocarcinomas in two research chemists in Germany (Bettendorf, 1976; Reznik, et al. 1977). One of the chemists was exposed for only two years; this individual was not involved with other known pulmonary carcinogens, although his contact with unspecified agents cannot be excluded (Reznik, et al. 1977).

In the United States, two of the best-known groups of cases occurred in an anion-exchange resin plant in California and a chemical manufacturing plant in Philadelphia. In the anion-exchange resin plant, five cases occurred among 136 manufacturing employees. Only 0.54 cases were expected among them if they were not exposed; thus, a 9.24-fold increase in the respiratory cancer risk was observed. The average age of cancer death was 47, and the mean induction time was 15 years (Lemen, et al. 1976). Heavy exposures to CMME, contaminated with BCME, occurred among workers in the Philadelphia chemical plant. In 1962, the management became aware that an excessive number of workers who were suspected of having lung cancers were reported in one area of the plant where CMME was used. Extensive prospective and retrospective studies have since been carried out independently by several groups of investigators (Figueroa, et al. 1973; Weiss and Figueroa, 1976; Weiss and Boucot, 1975; Weiss, 1976; DeFonso and Kelton, 1976). The latest figure

shows that a total of 20 cases of respiratory cancer deaths had occurred (DeFonso and Kelton, 1976). In one of the prospective studies including 88 exposed workers, an increased risk of 7.96 was observed (Figueroa, et al. 1973). A more recent analysis on an age-specific basis revealed an increased risk of lung cancer 3.8 times higher in 669 exposed compared to 1,616 unexposed workers (DeFonso and Kelton, 1976).

An extensive retrospective cohort mortality study of the respiratory cancer death among employees of six of the seven major users and producers of CMME in the U.S. has been carried out by Albert, et al. (1975) and Pasternack, et al. (1977). The cohort chosen included 1,827 exposed workers and 8,870 controls. The age-adjusted respiratory cancer death rate for the exposed group as a whole was found to be 2.53 times that in the control group, whereas death rates due to other causes were comparable. Most of the CMME-related deaths were associated with one of the six industrial firms in which heavy exposures occurred. Among workers who were reported to be heavily exposed for more than five years, a 23.7-fold increase in the respiratory cancer risk was observed (Albert, et al. 1975). The increased risk was clearly dependent on the duration and intensity of exposure. Based on job description, personnel records, and information supplied by the supervisory personnel, Pasternack, et al. (1977) estimated the duration (years) and cumulative weighted exposure index (duration of exposure X intensity) of workers and compared with their relative respiratory cancer risk. As shown in Table 21, there was a clear dose-response relationship. The linear trend χ^2 tests gave a highly significant

TABLE 21

Relationship of Respiratory Cancer Mortality to Duration
and Intensity of Exposure to BCME and/or CMME*

Duration of Exposure (years)	Observed Deaths	Expected Deaths	Relative Risk	Man-year-at-risk
10-19	3	0.2	26.6	97
5-9.9	7	1.9	6.0	1,024
2-4.9	10	2.8	5.7	1,981
0.1-1.9	3	6.7	0.7	5,591
Control	18	29.4	1.0	21,909

Cumulative Weighted Exposure Index**	Observed Deaths	Expected Deaths	Relative Risk	Man-year-at-risk
20-50	8	0.9	14.5	482
10-19.9	8	2.4	5.4	1,398
5-9.9	4	1.6	4.2	1,176
0.1-4.9	3	0.7	0.7	5,637
Control	18	29.4	1.0	21,909

* Source: Pasternack, et al. (1977)

**CWEI = Duration of Exposure x Intensity (varying across exposure periods)

p-value of less than 0.00001. Similar dose-response relationships were reported by DeFonso and Kelton (1976), and Weiss and Figueroa (1976). Thus, there is no doubt that BCME and CMME are potent human respiratory carcinogens.

CRITERION FORMULATION

Existing Guidelines and Standards

Both BCME and CMME have been recognized as human carcinogens; all contact with them should be avoided. In 1973, these two chloroalkyl ethers were listed as 2 of the 14 carcinogens restricted by Federal regulation. Emergency temporary standards were established for limiting occupational exposure. These regulations applied to all preparations containing 1 percent (w/w) or more of the chloroalkyl ethers. The use, storage, or handling of these chemicals must be limited to a "controlled area" in which elaborate precautions were specified to minimize worker exposure. Decontamination, waste disposal, monitoring, and medical surveillance programs were also required (38 FR 10929). More detailed regulations have recently been established; they apply to all preparations containing 0.1 percent of the chloroalkyl ethers by volume or weight (39 FR 3756; Anonymous, 1974). Based on the known carcinogenicity of BCME in animal inhibition studies, the American Conference of Governmental and Industrial Hygienists (ACGIH, 1978) has recommended a threshold limit value (TLV) of 1 ppb ($4.71 \mu\text{g}/\text{m}^3$) for BCME. This value is for the time-weighted average (TWA) concentration for a normal 8-hour workday or 40-hour workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect.

The Federal standard for BCEE is 15 ppm ($90 \text{ mg}/\text{m}^3$) (Tabershaw, et al. 1977). The ACGIH has recommended a time-weighted-average threshold limit value (TLV-TWA) of 5 ppm ($30 \text{ mg}/\text{m}^3$) for BCEE. For a short-term exposure limit, the tentative value (TLV-STEL) suggested

is 10 ppm (60 mg/m³). These values are based on the irritant properties of the chemical to the eye and the respiratory tract. It is also recommended that appropriate measures should be taken for the prevention of cutaneous absorption (ACGIH, 1978). The guideline level adopted by the Philadelphia regional office of U.S. EPA for BCEE level permitted in Philadelphia's drinking water is 0.02 µg/l. This value is based on an evaluation of the available toxicological data for BCEE by the National Environmental Research Center; a safety factor of 500,000 has been applied in the calculation (Manwaring, et al. 1977).

The TLVs for the other chloroalkyl ethers are not available. The provisional operational limit suggested for BCIE was 15 ppm (Gage, 1970). The value was based on the irritant properties of the compound to the eye and respiratory tract.

Current Levels of Exposure

There is no information available on the levels of chloroalkyl ethers in food or in the atmosphere; hence, no estimates can be made of the extent of human exposures to these compounds via these two routes. Information on the dermal exposure is also virtually nonexistent. Only incomplete data are available for the calculation of exposure via ingestion of drinking water; therefore, only rough estimates can be made. The highest concentration of BCEE, BCIE, and BCEXE in drinking water reported by U.S. EPA (1975) was 0.5, 1.58 and 0.03 µg/l, respectively. Assuming that (1) these values are representative of yearly averages, (2) the average daily intake of water is 2 liters, and (3) the average body weight is 70 kg, then the maximum possible daily exposure from water to BCEE,

BCIE, and BCEXE would be 14.3, 45.1, and 0.86 ng/kg. These values are, of course, the upper limits and are based on the dubious assumption that the highest value is representative of the yearly average and that they only apply to specific contaminated areas. For national averages, the data of Dressman, et al. (1977) and U.S. EPA (1977) may be used. The national average concentration of BCEE or BCIE in drinking water is calculated as the mean concentration multiplied by the percent incidence of occurrence. Thus, the average concentration in drinking water of BCEE and BCIE was respectively 11.5 ng/l (0.1 µg/lx11.5 percent), and 12.1 ng/l (0.17 µg/lx7.1 percent) in phase II and 1.7 ng/l (0.024 µg/lx7.27 percent) and 7.0 ng/l (0.11 µg/lx6.36 percent) in phase III. Using the same three assumptions mentioned above, the estimated daily exposure to BCEE and BCIE would be, respectively, 0.33 ng/kg and 0.35 ng/kg in phase II and 0.05 ng/kg and 0.20 ng/kg in phase III.

Special Groups at Risk

Exposure to BCME and CMME appears to be confined to occupational settings. A partial list of occupations in which exposure may occur includes: ion-exchange resin makers, specific organic chemical plant workers, laboratory workers, and polymer makers (Tabershaw, et al. 1977). Of these groups, workers in small noncommercial laboratories should probably be particularly cautious because of the lack of monitoring and surveillance and because of the fact that this group is more likely to be relatively more heavily exposed. Potential exposure to BCME may also occur in workplaces where vapors of hydrochloric acid and formaldehyde may coexist. The National Institute for Occupational Safety and Health has

already found trace levels of BCME in the textile industry. Other such places include biological, medical and chemical laboratories, and particle-board and paper manufacturing plants (Lemen, et al. 1976).

Exposure to β -chloroalkyl ethers may occur in residents in areas where the source of drinking water is from the contaminated river water and the treatment of drinking water is inadequate to remove the contaminants. Individuals consuming the water in these areas may be at a greater risk than the general population. Occupational exposure to BCEE may also occur. A partial list of occupations in which exposure may occur includes: cellulose ester plant workers, degreasers, dry cleaners, textile scourers, varnish workers, and processors or makers of ethyl cellulose, fat, gum, lacquer, oil, paint, soap, and tar (Tabershaw, et al. 1977).

Basis and Derivation of Criteria

There is no empirical evidence that BCIE is carcinogenic. However, because of its mutagenic activity and its close structural similarity to BCEE - which some studies have shown to be carcinogenic in mice - the possible carcinogenicity of BCIE is a matter of concern. The National Toxicology Program is currently re-testing this compound in mice by gavage and the results of this study should be reviewed as soon as they become available.

In the interim, a toxicity based criterion can be derived from the NCI bioassay using nontumor pathology which is summarized in Table 7. The lowest dose tested which caused minimum adverse effects was 10 mg/kg/day for the mice. At this dose, there was an increased incidence of centrilobular necrosis of the liver which

was not seen in the high-dose group. Because of concern for potential carcinogenicity and the failure of this study to define a positive dose/response relationship, a safety factor of 1,000 would seem justified. In addition, because the low dose group defines a LOAEL rather than a NOAEL, an additional safety factor of 10 is recommended. Assuming a 70 kg body weight for humans, the ADI can be calculated as:

$$\text{ADI} = 10 \text{ mg/kg/day} \times 70 \text{ kg}/10,000 = 70 \text{ }\mu\text{g/day}$$

Using the estimated bioconcentration factor of 2.47 for BCIE and assuming a daily consumption of 0.0065 kg fish and 2 liters of water, a criterion of 34.7 $\mu\text{g/l}$ may be calculated:

$$C = \frac{70 \text{ }\mu\text{g}}{2 + (0.0065 \times 2.47)} = 34.7 \text{ }\mu\text{g/l}$$

Because this criterion is based on a LOAEL and on a study in which a positive dose/response relationship was not noted, it should be regarded as a very imprecise approximation at best. The criterion should be revised as soon as better data become available.

In summary, based on the use of chronic mouse toxicological data and an uncertainty factor of 10,000, the criterion level of bis(2-chloroisopropyl) ether corresponding to an acceptable daily intake of 10 mg/kg is 34.7 $\mu\text{g/l}$. Drinking water contributes 99 percent of the assumed exposure, while eating contaminated fish products accounts for 1 percent. The criterion level can similarly be expressed as 4.36 mg/l if exposure is assumed to be from the consumption of fish and shellfish products alone.

The estimated safe level of BCEE in drinking water may be calculated using the linearized multistage model as discussed in the

Human Health Methodology Appendices to the October 1980 Federal Register notice which announced the availability of this document. The data of Innes, et al. (1969) on the carcinogenicity of this compound by oral administration to male mice are used in the calculation. The bioaccumulation factor for BCEE is 6.9. Based on this approach, the calculated water quality criterion for BCEE is 0.30 ug/l. Compliance to this level should limit human lifetime risk of carcinogenesis from BCEE in ambient water to not more than 10^{-5} (one case in 100,000 persons at risk). It should also very adequately protect against noncarcinogenic toxicity since the daily dose of contaminant that would be absorbed from water containing the criterion limit is many times less than the minimal daily oral dose required to produce a detectable toxic response in animals.

The setting of drinking water standards for BCME and CMME would be of academic interest only, since these α -chloroalkyl ethers may not, under ordinary conditions, exist in water for periods of time longer than a few hours. Carcinogenicity data generated by oral administration of these compounds are not available.

In the case of CMME, no criterion was calculated due to its extremely short half-life in aqueous solution. Jones and Thornton (1967) have measured the hydrolysis rate of CMME in aqueous isopropanol. Extrapolation of the data to pure water yielded a $t_{1/2}$ of less than one second. BCME has a slightly longer half-life. Therefore, as a guideline, the safe level of BCME in drinking water may be calculated using the tumor incidence data from chronic rat inhalation studies (Kuschner, et al. 1975). In this study, Sprague-Dawley rats were exposed to various doses of BCME six hours per day, five

days per week throughout their lifetime. The validity of the incidence rates for humans was established by evaluating the cancer incidence in workers after accounting for their exposure (Pasternack, et al. 1977).

Therefore, using the linearized multistage model as previously described and a bioconcentration factor of 0.63, the recommended maximum permissible concentration of BCME for the ingested water is 0.038 ng/l. Compliance to this level should limit human lifetime risk of carcinogenesis from BCME in ambient water to not more than 10^{-5} .

Under the Consent Decree in NRDC v. Train, criteria are to state "recommended maximum permissible concentrations (including where appropriate, zero) consistent with the protection of aquatic organisms, human health, and recreational activities." BCEE and BCME are suspected of being human carcinogens. Because there is no recognized safe concentration for a human carcinogen, the recommended concentration of these chloroalkyl ethers in water for maximum protection of human health is zero.

Because attaining a zero concentration level may be infeasible in some cases and in order to assist the Agency and states in the possible future development of water quality regulations, the concentrations of BCEE and BCME corresponding to several incremental lifetime cancer risk levels have been estimated. A cancer risk level provides an estimate of the additional incidence of cancer that may be expected in an exposed population. A risk of 10^{-5} , for example, indicates a probability of one additional case of cancer for every 100,000 people exposed, a risk of 10^{-6} indicates one

additional case of cancer for every million people exposed, and so forth.

In the Federal Register notice of availability of draft ambient water quality criteria, the U.S. EPA stated that it is considering setting criteria at an interim target risk level of 10^{-5} , 10^{-6} , or 10^{-7} as shown in the following table.

<u>Exposure Assumptions</u> (daily intake)	<u>Risk Levels</u> <u>and Corresponding Criteria (1)</u>		
	10^{-7} ($\mu\text{g/l}$)	10^{-6} ($\mu\text{g/l}$)	10^{-5} ($\mu\text{g/l}$)
2 liters of drinking water and consumption of 6.5 g of fish and shellfish (2)			
Bis(2-chloroethyl)ether	0.003	0.030	0.30
Bis(chloromethyl)ether	0.376×10^{-6}	3.76×10^{-6}	37.6×10^{-6}
Consumption of fish and shellfish only			
Bis(2-chloroethyl)ether	0.136	1.36	13.6
Bis(chloromethyl)ether	0.184×10^{-3}	1.84×10^{-3}	18.4×10^{-3}

(1) Calculated by applying a linearized multistage model as discussed in the Human Health Methodology Appendices to the October 1980 Federal Register notice which announced the availability of this document. Appropriate bioassay data used in the calculation are presented in Appendix I. Since the extrapolation model is linear at low doses, the additional lifetime risk is directly proportional to the water concentration. Therefore, water concentrations corresponding to other risk levels can be derived by multiplying or dividing one of the risk levels and corresponding water concentrations shown in the table by factors such as 10, 100, 1,000, and so forth.

(2) Two percent of BCEE exposure results from the consumption of aquatic organisms which exhibit an average bioconcentration potential of 6.9-fold. The remaining 98 percent of BCEE exposure results from drinking water.

Two-tenths percent of BCME exposure results from the consumption of aquatic organisms which exhibit an average bioconcentration potential of 0.63-fold. The remaining 99.8 percent of BCME exposure results from drinking water.

Concentration levels were derived assuming a lifetime exposure to various amounts of BCIE, BCEE, and BCME, (1) occurring from the consumption of both drinking water and aquatic life grown in water containing the corresponding chloroalkyl ether concentrations and, (2) occurring solely from consumption of aquatic life grown in the waters containing the corresponding chloroalkyl ether concentrations.

Although total exposure information for these chloroalkyl ethers is discussed and an estimate of the contributions from other sources of exposure can be made, this data will not be factored into the ambient water quality criteria formulation because of the tenuous estimates. The criteria presented, therefore, assume an incremental risk from ambient water exposure only.

APPENDIX I

Summary and Conclusions Regarding the Carcinogenicity of Chloroalkyl Ethers*

Chloroalkyl ethers have a wide variety of industrial and laboratory uses in organic synthesis, treatment of textiles, manufacture of polymers and insecticides, and as degreasing agents. Bis(chloromethyl)ether (BCME) and chloromethylmethyl ether (CMME) have been included in the Occupational Safety and Health Administration's (OSHA) list of restricted chemicals (1974) based on animal studies and human epidemiological evidence indicating that these compounds are carcinogenic by inhalation. An additional occupational hazard is the spontaneous combination at high concentrations of vapors of HCL and formaldehyde to form BCME. Bis(2-chloroethyl)ether (BCEE) is present in rivers and drinking water in several cities and is found in high concentrations in waste water from chemical plants.

Several of the chloroalkyl ethers including BCME, CMME, BCEE, and BCIE were mutagenic in bacterial systems without metabolic activation, indicating that they are direct-acting mutagens. Data for BCME, CMME, and BCEE indicate furthermore, that these compounds are both mutagenic and carcinogenic.

BCME has been shown to be carcinogenic in animals following inhalation or dermal exposure. In an inhalation study by Kuschner, et al. (1975), BCME induced malignant tumors of the respiratory tract in male Sprague-Dawley rats. Application of BCME to mouse

*This summary has been prepared and approved by the Carcinogens Assessment Group, EPA, on July 20, 1979.

skin induced skin tumors (van Duuren, et al. 1968), while s.c. injection of BCME to newborn ICR Swiss random-bred mice induced pulmonary tumors (Gargus, et al. 1969). There were no studies reported using oral administration of BCME.

The carcinogenicity of BCEE by oral administration was investigated by Innes, et al. (1969) in two strains of mice. There was a statistically significant increase of hepatomas in the male mice of both strains (C57BL/6 x C3H/Anf)_{F₁} and (C57BL/6 x AKR)_{F₁}, respectively, and in the female mice of one strain (C57BL/6 x C3H/Anf)_{F₁}.

Epidemiological studies of workers in the United States, Germany, and Japan who were occupationally exposed to BCME and/or CMME (chloromethylmethyl ether) have indicated that these compounds are human respiratory carcinogens.

The water quality criterion for BCEE is based on the results of the Innes study in which hepatomas were induced in mice given a daily oral dose of 300 ppm (i.e., 39 mg/kg/day). The concentration of BCEE in drinking water calculated to limit human lifetime cancer risk from BCEE to less than 10^{-5} is 0.30 µg/l.

There is no carcinogenicity data from oral exposure to BCME. The rapid hydrolysis rate of BCME in water precludes a realistic exposure. However, a criterion is calculated in the event that levels are monitored in the water. Since BCME is a locally acting carcinogen and it is expected that the stomach would be the target organ from oral exposure, the lung tumor data from the inhalation study was accepted for estimating human risk, and 100 percent absorption of BCME was assumed. The water quality criterion was calculated using data from the Kushner, et al. inhalation study,

where rats given 100 exposures of various doses of BCME for six hours per day, five days per week, developed malignant respiratory tract tumors. The concentration of BCME calculated to maintain lifetime cancer risk below 10^{-5} is 0.038 ng/l.

Bis(2-Chloroethyl)ether

The water quality criterion for BCEE is based on the induction of hepatomas in male mice (strain C57BL/6 x C3H/Anf)_{F₁} given a daily oral dose of 300 ppm for 80 weeks (Innes, et al. 1969). The criterion was calculated from the following parameters:

<u>Dose</u> <u>(mg/kg/day)</u>	<u>Incidence</u> <u>(no. responding/no. tested)</u>
0	8/79
39	14/16

le = 560 days

w = 0.030 kg

Le = 560 days

R = 6.9 l/kg

L = 560 days

With these parameters, the carcinogenic potency factor for humans, q_1^* , is $1.144 \text{ (mg/kg/day)}^{-1}$. The resulting water concentration of BCEE calculated to keep the individual lifetime cancer risk below 10^{-5} is $0.30 \text{ } \mu\text{g/l}$.

Bis(Chloromethyl)ether

The water quality criterion for BCME is based on the induction of malignant respiratory tract tumors in male Sprague-Dawley rats given 100 exposures of various doses of BCME by inhalation six hours per day, five days per week (Kuschner, et al. 1975). The criterion was calculated from the following parameters:

<u>Dose</u> <u>(mg x 10⁻⁴ /kg/day)</u>	<u>Incidence</u> <u>(no. responding/no. tested)</u>
0.0	0/240
0.35	1/41
0.70	3/46
1.4	4/18
2.1	4/18
2.8	15/34
3.5	12/20

le = 728 days

w = 0.500 kg

Le = 728 days

R = 0.63 l/kg

L = 728 days

With these parameters, the carcinogenic potency factor for humans, q_1^* , is $9299.8 \text{ (mg/kg/day)}^{-1}$. The resulting water concentration of BCME calculated to maintain the individual lifetime cancer risk below 10^{-5} is 0.038 ng/l.
